>
> Dear Dr. Tuholske,
>
> We are pleased to inform you that the PNAS Editorial Board has given final approval of your article for publication. Matei Georgescu, the Editor who conducted the initial review of your manuscript [MS# 2020-24792RR], will also be informed of the decision.
>
> The editorial staff may contact you shortly if final publication ready files are needed. Please note you may be asked to shorten your manuscript upon receipt of the article proof if the work does not adhere to the stated length requirements and additional fees may apply.
>
> Within 48 hours of receipt of your proofs, you will receive an email from PNAS with a link to your publication charge estimate in our online billing platform. Please see the PNAS Author Center for information about publication fees. Authors of research articles may pay a surcharge to make their paper freely available through the PNAS Open Access option. If your institution has a current Site License, the open access surcharge is discounted. Brief Report publication fees include Open Access. Proofs should be returned within 48 hours.
>
> Papers "in press" at PNAS are under embargo and not for public release before 3:00 PM Eastern Time, the Monday before publication. Authors may talk with the press about their work prior to the embargo but should

coordinate this with the PNAS News Office or their institution's press office so that reporters are aware of PNAS policy and understand that papers are embargoed until the week of publication. If you plan to present your embargoed paper at a conference prior to publication, please contact the PNAS News Office immediately at 202-334-1310, or PNASnews@nas.edu.

Authors are invited to submit scientifically interesting and visually arresting cover illustrations. To view accepted cover art, please visit the PNAS cover archive. Please note that images must be original and that exclusive rights to publish will convey to PNAS. If selected for the cover, the image also may be used further in promotional materials, including but not limited to brochures, advertisements, and posters. To submit cover art candidates, please send files to PNASCovers@nas.edu

If you provided your ORCID iD when submitting your manuscript, you can opt in to have your ORCID record automatically updated when your article is published. You will need to watch for an email from Crossref in your ORCID Inbox requesting permission to access your ORCID record and grant Crossref permission.

Yours,
May R. Berenbaum
Editor-in-Chief

Abstract:
Increased exposure to extreme heat from both climate change and the urban heat island effect – total urban warming – threatens the sustainability of rapidly growing urban settlements worldwide. Extreme heat exposure is highly unequal, with the urban poor most severely impacted. While previous studies have quantified global exposure to extreme heat, the lack of a globally comparable, accurate, and fine-resolution temporal analysis of urban exposure crucially limits our ability to deploy adaptations. Here we estimate daily urban population exposure to extreme heat for 13,115 urban settlements from 1983 to 2016. We harmonize new global, fine-resolution (0.05°) daily temperature maxima and relative humidity estimates with the first geo-located and longitudinal global urban population database. We measure the average annual rate of increase in exposure (person-days yr^{-1}) at the global, regional, national, and municipality-level, separating the contribution to exposure trajectories from urban population growth versus total urban warming. Using a daily maximum wet bulb globe temperature threshold of 30°C, global exposure increased nearly 200% from 1983 - 2016 and total urban warming elevated the annual increase in exposure by 52% compared to urban population growth alone. Exposure trajectories increased for nearly half of urban settlements, which together in 2016 comprised over a fifth of the planet's population, or 1.7 billion people. However, how total urban warming and population growth drove exposure trajectories is spatially heterogeneous. This study reinforces the importance of employing multiple extreme heat exposure metrics to identify local patterns and compare exposure trends across geographies. Our results suggest that previous research underestimates extreme heat exposure, highlighting the urgency for targeted adaptations and early warning systems to reduce harm from urban extreme heat exposure.

Significance statement:
Increased extreme heat exposure from both climate change and the urban heat island effect threatens rapidly growing urban settlements worldwide. Yet, because we do not know where urban population growth and extreme heat intersect, we have limited capacity to reduce the impacts of urban extreme heat exposure. Here we leverage new, fine-resolution temperature and population data to measure urban extreme heat exposure for 13,115 cities from 1983 - 2016. Globally, urban exposure increased nearly 200%, affecting 1.7 billion people. Total urban warming elevated exposure rates 52% above population growth alone. However, spatially heterogeneous exposure patterns highlight an urgent need for locally tailored adaptations and early warning systems to reduce harm from urban extreme heat exposure across the planet's diverse urban settlements.

MAIN TEXT

Introduction:

Increased exposure to extreme heat from both climate change (1–5) and the urban heat island (UHI) effect (6–9) threaten the sustainability of rapidly growing urban settlements worldwide. Exposure to dangerously high temperatures endangers urban health and development, driving reductions in labor productivity and economic output (10, 11) and increases in morbidity (1) and mortality (3, 4, 12). Within urban settlements, extreme heat exposure is highly unequal and most severely impacts the urban poor (13, 14). Despite the harmful and inequitable risks, we presently lack a globally comprehensive, fine-resolution understanding of where urban population growth intersects with increases in extreme heat (3, 6, 15). Without this knowledge, we have limited ability to tailor adaptations to reduce extreme heat exposure across the planet's diverse urban settlements (6, 15, 16).

Reducing the impacts of extreme heat exposure to urban populations requires globally consistent, accurate, and high-resolution measurement of both climate and demographic conditions that drive exposure (2, 15, 17). Such analysis provides decision makers with information to develop locally-tailored interventions (7, 18, 19) and is also sufficiently broad in spatial coverage to transfer knowledge across urban geographies and climates (6). Information about exposures and interventions from diverse contexts is vital for the development of functional early warning systems (20) and can help guide risk assessments and inform future

scenario planning (21). Existing global extreme heat exposure assessments (1, 3), however, do not meet these criteria (Table S1) and are insufficient for decision makers. These studies are coarse-grained (>0.5° spatial resolution), employ disparate or single metrics that do not capture the complexities of heat-health outcomes (22), do not separate urban from rural exposure (19), and rely on climate reanalysis products that can be substantially (~1 to 3°C) cooler than in-situ data observations (2, 23, 24). In fact, widely-cited benchmarks (25) that estimate extreme heat with the version 5 of the European Centre for Medium-Range Weather Forecasts Reanalysis (ERA5) (26) may greatly underestimate total global exposure to extreme heat (2, 23, 24). Using a 40.6°C daily maximum 2m air temperature threshold (T_{max}), recent analysis found that ERA5 T_{max} drastically underestimated the number of extreme heat days per year compared to in-situ observations (23). Finally, few studies (3, 18) have assessed urban extreme heat exposure across data-sparse (23) rapidly urbanizing regions, such as Sub-Saharan Africa, the Middle East, and Southern Asia (27), that may be most impacted by increased extreme heat events due to climate change (2, 4, 28).

Here we present the first globally comprehensive, fine-resolution, and longitudinal estimate of urban population exposure to extreme heat—referred to henceforth as *exposure*—for 13,115 urban settlements from 1983 to 2016. To accomplish this, we harmonize new global, fine-grained (0.05° spatial resolution) T_{max} estimates (23) with new global urban population and spatial extent data (29). For each urban settlement, we calculate area-averaged daily maximum wet bulb globe temperature ($WBGT_{max}$) (30) and heat index maxima HI_{max} (31) using CHIRTS-daily T_{max} (23) and down-scaled daily minimum relative humidity (RH_{min}) estimates (32). CHIRTS-daily is better suited to measure urban extreme heat exposure than other gridded

temperature datasets used in recent global extreme heat studies (Table S1) for two reasons. First, it is more accurate, especially at long distances (See Fig. 3 in (23)), than widely-used gridded temperature datasets to estimate urban temperature signals worldwide (Fig. S1-S2). Second, it better captures the spatial heterogeneity of T_{max} across diverse urban contexts (Fig. S3). These factors are key for measuring extreme heat exposure in rapidly urbanizing, data-sparse regions.

As discussed in (23, 24), the number of in situ temperature observations is far too low across rapidly-urbanizing (27) regions to resolve spatial and temporal urban extreme heat fluctuations, which can vary dramatically over small distances and time periods. For example, of the more than 3,000 urban settlements in India (29), only 111 have reliable station observations (Fig. S3). While climate reanalyses can help overcome these limitations, they are coarse-grained (Table S1), suffer from mean bias, and, to a lesser degree, temporal fidelity. ERA5 has been shown to substantially underestimate the increasing frequencies of heat extremes (Fig. 4 in (23)), while Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA2) fails to represent the substantial increase in recent monthly T_{max} values (Fig. 8 in (24)). These datasets dramatically underestimate increases in warming. CHIRTS-daily overcomes these limitations by coherently stacking information from a high-resolution climatology (0.05°) derived surface emission temperatures (24), interpolated in situ observations, and ERA5 reanalysis to produce a product that has been explicitly developed to monitor and assess temperature related hazards (23). As such, CHIRTS-daily is best suited to capture variation in exposure across urban settlements in rapidly urbanizing (27), data-sparse regions such as Sub-Saharan Africa, the Middle East, and Southern Asia (Fig. S3) (24).

We measure exposure in person-days yr^{-1} – the number of days per year that exceed a heat exposure threshold multiplied by the total urban population exposed (2). We then estimate annual rates of increase in exposure at the global (Fig. 1), regional (Table S2), national (Table S3), and municipality levels from 1983 - 2016 (Table S4). At each spatial scale, we separate the contribution to exposure trajectories from total urban warming and population growth (2). For clarity, *total urban warming* refers to the combined increase of extreme heat in urban settlements from both the UHI effect and anthropogenic climate change. We do not decouple these two forcing agents (33, 34). However, we identify which urban settlements have warmed the fastest by measuring the rate of increase in the number of days per year that exceed the two extreme heat thresholds described below (*15*). Our main findings use an extreme heat exposure threshold defined as $WBGT_{max}$ >30°C, the International Standards Organization (ISO) occupational heat stress threshold for risk of heat-related illness among acclimated persons at low metabolic rates (100-115W) (30). $WBGT_{max}$ is a widely used heat stress metric (36) that captures the biophysical response (35) of hot temperature-humidity combinations (4, 17) that reduce labor output (35), lead to heat related illness (35) and can cause death (23). In using a threshold $WBGT_{max}$ >30°C, which has been associated with higher mortality rates among vulnerable populations (37), we aim to identify truly extremely hot temperature-humidity combinations (17) that can harm human health and wellbeing. We recognize, however, that strict exposure thresholds do not account for individual-level risks and vulnerabilities related to acclimatization, socio-economic or health status or local infrastructure (18, 19, 38). We also note that there are a range of definitions of exposure and we provide further analysis identifying 2-day or longer periods where the

maximum heat index (HI_{max}) (31) exceeded 40.6°C (Fig. S4-S6) following the US National Weather Service's definition for an excessive heat warning (39).

Results and Discussion:

Global exposure increased 199% in 34-years, from 40 billion person-days in 1983 to 119 billion person-days in 2016, growing by 2.1 billion person-days yr^{-1} (Fig. 1A). Population growth (Fig. 1B) and total urban warming (Fig. 1C) contributed 66% (1.5 billion person-days yr^{-1}) and 34% (0.7 billion person-days yr^{-1}) to the annual rate of increase in exposure, respectively. That is, total urban warming elevated the global annual rate of increase in exposure by 52% compared to urban population growth alone. This finding is not directly comparable to recent global benchmarks and projections of total population exposure to extreme heat because of disparate exposure definitions employed (Table S1). However, our results indicate much higher exposure rates compared to recent continental-scale benchmarks. Defining exposure as the total population multiplied by the number of days per year where $HI_{max} > 40.6°C$, a recent study found that the total annual average exposure from 1986 - 2005 for 173 African cities was 4.2 billion person-days yr-1 (40). When we apply the same exposure criteria to our data, including parameterizing HI_{max} with daily average RH instead of RH_{min}, we find six times the average total exposure for Africa, or 27.5 billion person-days yr^{-1}, over the same time period. This contrasting exposure estimate showcases how the increased spatial and temporal accuracy of CHIRTS-daily T_{max} (Fig. S1-S3), combined with the increased granularity of urban settlement data we employ (29), can better capture exposure trends in data-sparse regions like Africa.

While just 25 urban settlements contributed nearly 25% of the global annual rate of increase in exposure (Table S3), we identify statistically significant ($p < 0.05$) positive exposure

trajectories from 1983 - 2016 for nearly half (5,985) of municipalities worldwide (Fig 2A). Together, these urban settlements comprised 23% of the planet's total population (27), or 1.7 billion people, in 2016 (27). The majority are concentrated in low-latitudes but span a range of climates. Additionally, 17% (2,252) of urban settlements added at least one day per year where $WBGT_{max}$ exceeded 30°C (Fig. 2B). In other words, these urban settlements experienced an additional month of extreme heat in 2016 compared to 1983. Remarkably, 21 urban settlements with populations greater than 1 million residents in 2016 added more than 1.5 days per year of extreme heat. This includes Kolkata, India, which is the capital of the state of West Bengal and housed 22 million people in 2016 (29). These findings suggest that increased extreme heat is potentially elevating mortality rates for many of the planet's urban settlements, especially among those most socially and economically marginalized (37). Globally, for every additional day T_{max} exceeds 35°C compared to 20°C, mortality increases by 0.45 per 100,000 people, with an increase of 4.7 extra deaths per 100,000 people for those above 64 years old (12).

Separating the contribution to exposure trajectories from urban population growth and total urban warming underscores how the level of analysis affects our understanding of the spatial distribution and magnitude of exposure. The level of analysis employed can either mask or highlight spatial and temporal patterns that are key to allocating limited resources for adaptations and sharing knowledge across urban contexts (2, 3, 6, 7). Broadly, we find that municipality-level exposure trajectories (Fig. 2C) reflect national and regional-level urbanization trends (27). In regions with slower urban population growth (27), like Latin America and the Caribbean (Fig. 3A) (27), the contribution of total urban warming to increases in exposure trajectories compared to urban population growth is largely responsible for increased exposure

for the majority of municipalities compared to regions with more rapid urban population growth. As urban population growth rates increase by region, the signal from total urban warming diminishes for most municipalities, as evident by Western Asia (Fig. 3B), Southern Asia (Fig. 3C), and sub-Saharan Africa (Fig 3D).

However, we detail striking spatial heterogeneity in how urban demographic and total urban warming signals drive exposure trajectories for individual municipalities, even those with similar population sizes and within the same country. As such, regional and national-level assessments designed to inform policy implementation (1, 41), may fail to capture municipality-level (and finer scale) nuances that are key for adaptations (7, 15) and future climate change scenario planning (21) (Supplementary Text, Fig. S7-S8). For example, in West Africa, while we find exposure trajectories increased for 88% of Nigerian urban settlements, the disparate influence of total urban warming across urban settlements may be dictated by local climate (Supplementary Text, Fig. S8). Furthermore, we map pockets of urban settlements in Southern India, the Ganges Delta, the Nile river valley and delta, and along the Tigris-Euphrates (Fig. 2C, Fig. S9)—all rapidly urbanizing regions (*1*)—where total urban warming exceeded urban population growth as the driver of exposure. This geographic pattern parallels recent global analysis of station observations of extreme humid heat that suggest areas of the planet may soon exceed human biophysical capacity, regardless of local acclimatization (17).

Among the clearest examples of the importance of differentiating urban demographic and total urban warming signals at the municipality-level comes from two Indian megacities: Delhi and Kolkata. Exposure trajectories for both cities are congruent (Table 3, Fig. S10A). But population growth contributed to nearly 75% of the increase in Delhi's exposure trajectory,

whereas population growth accounted for only 48% of the annual rate of increase in exposure in Kolkata (Table S4, Fig. S10B-C). The stark contrast in the impact of total urban warming versus urban population growth on the two cities' exposure trajectories (Fig. S10) reinforces that individual adaptations require fine-grained spatiotemporal, yet globally comparable, analysis (6, 15). Such precision is crucial for decision makers given the range of adaptation choices and costs (7, 15), and also opens new avenues of inquiry to examine linkages between elevated temperatures, changes in humidity, and drivers of urban population growth (16, 42–45).

Finally, while our main findings focus on exposure determined by $WBGT_{max}$>30°C, we showcase the contrast between $WBGT_{max}$ and HI_{max} exposure estimates with two examples of poorly documented local urban extreme heat events. First, air temperatures that reached 49.8°C reportedly killed thousands of people in India in 1998 (46). But the reports do not specify nor identify impacts specific to urban settlements. In Kolkata, which was home to 12 million people in 1998 (27), we find that HI_{max} exceeded 40.6°C for 53 consecutive days in May - June 1998 (Fig. 4A). During this period the average HI_{max} exceeded the 34-year daily HI_{max} average by as much as 9°C. (27). The amplitude of daily extreme temperature-humidity combinations however, is not resolved using $WBGT_{max}$ (Fig. 4B) because $WBGT_{max}$ saturates at high values (47).

Next, we examine the summer of 2010 in Syria, which was the final year of a 4-year drought that was 2 to 3 times more likely because of climate change (48). In Aleppo, home to 3 million people in 2010 (27), we document an 8-day period shortly followed by a 7-day period with HI_{max} above 40.6°C (Fig. 4C). We isolate the peak of the heat wave hitting Aleppo on Aug. 5, during which HI_{max} exceeded 47°C (9°C above average HI_{max} for Aug. 5) and marked the second hottest day in the entire 34-year record. Yet, like Kolkata in 1998, the amplitude of the

extreme heat events in Aleppo in 2010 is not captured by $WBGT_{max}$ compared to HI_{max} (Fig. 4D). While the likelihood of heat waves has increased for the Eastern Mediterranean since the 1960s (49), to our knowledge, urban extreme heat during the summer of 2010 in Syria has not been documented nor quantified until now. This extreme heat event occurred six months prior to the beginning of the Syrian uprising. While conflict and climate linkages are inconclusive and complex (50, 51), this finding from Aleppo illustrates potential advantages of higher-resolution data and analysis we present here for future research to examine climate-conflict linkages.

We present these examples not to advocate for or against the use of either $WBGT_{max}$ or HI_{max} to measure exposure. Both have limitations when independently used to quantify extreme heat exposure. HI_{max} was not intended to estimate heat exposure above HI_{max}~50°C (52) and the quadradic relationship we used to convert HI_{max} to $WBGT_{max}$ explains the asymptotic ceiling of $WBGT_{max}$ and its failure to capture daily extremes like HI_{max} does (47). Rather we join the growing community of scholars advocating for the use of multiple (22), place-based heat wave metrics that inform and create better synergies across research domains (19). Locally-defined exposure criteria (18) are especially useful for early warning systems (53) when tied to biophysical response of extreme heat with impacts on individual-level human health and wellbeing (19, 22), as well as be comparable across geographies (6).

By focusing on extremely hot-humid exposure defined by (6) >30°C, our global synthesis of urban extreme heat exposure is conservative. For example, when we adjust the threshold to (6) $WBGT_{max}$>28°C (Fig. S11), the ISO occupational standard risk for heat-related illness for acclimated people at moderate metabolic rates (235-360W) (30), 7,628 urban settlements have a significant ($p < 0.05$) in exposure from 1983 - 2016 (Fig. S11). In contrast, when we adjust the

threshold to $WBGT_{max}$ >32°C, the ISO heat-risk threshold for unacclimated people at resting metabolic rates (100-125W) (30), 2,979 urban settlements have a significant ($p < 0.05$) increase in exposure from 1983 – 2016 (Fig. S11). Accordingly, our findings suggest that in already hot regions, like the Sun Belt Region in the United States, where air temperatures are projected to increase (18), temperature-humidity (6) combinations may not regularly exceed extremes like $WBGT_{max}$ >32°C for many urban settlements. For example, take Phoenix, Arizona. The hottest T_{max} ever recorded in Phoenix was 122°F on June 26, 1990 at 23h GMT (54, 55). The relative humidity at that time was 11% (54). Following our methods, the HI_{max} equivalent was 49°C and the equivalent $WBGT_{max}$ was 32.29°C. Thus, vulnerable population regularly experience extreme heat exposure in Phoenix (56, 57), demonstrating the need for diverse definitions of heat stress.

In sum, our analysis calls into question the future sustainability and equity for populations living in and moving to many of the planet's urban settlements. Climate change is increasing the frequency, duration, and intensity of extreme heat across the globe (1–5). Indeed, combined temperature and humidity extremes already exceed human biophysical tolerance in some locations (17). Poverty reduction in urban settlements ultimately hinges on increasing labor productivity (10) but, across spatial scales, elevated temperatures have been associated with decreased economic output (11, 58, 59). As such, the spatial pattern of exposure trajectories we identify in Africa and Southern Asia, which already house hundreds of millions of the urban poor (60), highlight that, without sufficient investment, humanitarian intervention, and government support, extreme heat may crucially limit the urban poor's ability to realize the economic gains associated with urbanization (61). Synthesizing extreme heat exposure across all individual urban settlements globally, however, reveals that exposure trajectories are composed of

thousands of extreme heat events. Each of those events presents an opportunity for effective early warning, a tool that, if widely implemented, can reduce the burden extreme heat places on all urban populations (20).

Materials and Methods:

Daily Temperature

The new Climate Hazards Center InfraRed Temperature with Stations Daily (CHIRTS-daily) provides globally extensive, high-resolution (0.05°) daily maximum and minimum temperature estimates (T_{max} and T_{min}) from 1983 – 2016 (23). CHIRTS-daily T_{max} and T_{min} are produced by bias correcting ERA5 T_{max} data with the monthly averaged T_{max} from the Climate Hazards center InfraRed Temperature with Stations ($CHIRTS_{max}$) climate data record (24). By combining cloud-screened harmonized geostationary satellite thermal infrared (TIR) observations with approximately 15,000 in-situ station observations from Berkeley Earth (62), $CHIRTS_{max}$ is the most accurate ($R^2 = 0.8 – 0.9$) high-resolution monthly maximum temperature datasets with global coverage (24). The advantage of $CHIRTS_{max}$ is that it captures T_{max} in rapidly urbanizing (27), yet data sparse regions (Fig. S1-S2). Indeed, from 1983 to 2016, station-based daily observations of temperature maxima declined globally from 5,900 to 1,000 (24). This decline was especially acute in Sub-Saharan Africa, the Middle East and Southern Asia, regions that have the fastest growing urban populations (27). Validation of CHIRTS-daily T_{max} against Global Historical Climatology Network and Global Summary of the Day databases show that CHIRTS-daily consistently outperforms the widely used Princeton University's Global Meteorological Forcing Dataset (PGF) for land surface modeling (Figs. S1-3) (63) as well ERA5 (26).

The methodology used to produce the CHIRTS-daily T_{max} relies on fusing the skill of $CHIRTS_{max}$ at measuring high-spatial resolution monthly climatology (24) with the ability of ERA5 T_{max} to measure daily temperature anomalies. To produce CHIRTS-daily T_{max}, first, ERA5 T_{max} and T_{min} are down-scaled from 0.25° latitude by 0.25° longitude to 0.05° by 0.05° using bilinear interpolation to match the spatial resolution of $CHIRTS_{max}$. Next, the ERA5 daily diurnal temperature range (DTR) is calculated by subtracting ERA5 daily T_{max} from ERA5 daily T_{min} (DTR) (eq. 1). ERA5 daily T_{max} are then converted to anomalies, by subtracting the ERA5 monthly T_{max} average from the daily ERA5 T_{max} value (eq. 2). The ERA5 T_{max} daily anomalies are then added to the $CHIRTS_{max}$ value for a given month (eq. 3). CHIRTS-daily T_{min} is produced by subtracting the ERA5 daily diurnal temperature (DTR) from CHIRTS-daily T_{max} (eq. 4). This process is repeated across all months and all days from 1983 - 2016 and can be expressed as

$$DTR_t = ERA5\ T_{max_t} - ERA5\ T_{min_t} \text{ for } t = 1 \ldots T \text{ (eq. 1)}$$

$$ERA5\ T^{m,\,anomn}_{max_t} = ERA5\ T^{t}_{max_t} - ERA5\ T^{m}_{\underline{max}} \text{ for } t = 1 \ldots T,\ m = 1 \ldots M \text{ (eq. 2)}$$

$$CHIRTS_{daily}\ T_{max} = CHIRTS_{max} + ERA5\ T^{m,\,anomn}_{max_t} \text{ (eq. 3)}$$

$$CHIRTS_{daily}\ T_{min} = CHIRTS_{daily}\ T_{max} - DTR_t \text{ (eq. 4)}$$

where T is all the days (t) in the CHIRTS-daily record and M is all the months (m) in the $CHIRTS_{max}$ record from 1983 – 2016.

Daily Relative Humidity Product

Because T_{max} generally occurs when RH is lowest during a diurnal cycle (32), daily relative humidity minimum fields (RH_{min}) are calculated (Eq. 5-7) by combining CHIRTS-daily T_{max} with downscaled ERA5 dew-point pressure (T_d) and surface pressure (p, kg / kg) from Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2). ERA5 T_d is downscaled from 0.25° longitude by 0.25° latitude and MERRA-2 p is downscaled from 0.5° latitude x 0.625° longitude to CHIRTS-daily's 0.05° by 0.05° spatial resolution using bilinear interpolation. To calculate RH_{min} (64), first we calculated specific humidity (q) as:

$$q = \left(0.622 \times e\right) \div (p - (0.378 \times e)) \text{ (Eq. 5)}$$

where vapor pressure in millibars (e), is:

$$e = 6.112 \times exp(\left(17.67 \times T_d\right) \div \left(T_d + 243.5\right) \text{ (Eq. 6)}$$

Daily RH_{min} is then calculated, as:

$$RH_{min} = 0.263 \times p \times q \div (exp(\left(17.67\left(T - T_0\right) \div T - 29.65\right)) \text{ (eq. 7)}$$

where T is the CHIRTS-daily T_{max} and T_0 is 273.15 to convert Kelvin to Celsius. The result is a fine-grain daily RH estimate for the entire planet from 1983 - 2016.

Population Data

We use population estimates and spatial boundaries for 13,115 urban settlements from the Global Human Settlement Layer Urban Centers Database (GHS-UCDB) released by the European Commission Joint Research Council in 2019 (29). Available as vector shapefiles, GHS-UCDB is derived from a gridded population modeling framework that apportions finest-available census data to grid cells based on built environment detected in the Landsat archive (for a complete description see ((29)). GHS-UCDB populations are benchmarked for 1975, 1990,

2000 and 2015. To estimate populations for each GHS-UCDB polygon for each year from 1983 - 2016, we apply a stepwise linear interpolation to the 1975, 1990, 2000, and 2015 GHS-UCDB population estimates for each urban settlement.

GHS-UCDB is the only well-documented global, geo-located urban population and extent dataset. We recognize that strict definitions of urban populations often fail to capture the urban-rural continuum (65), nor the wide diversity and variation within and between urban settlements across the planet (66). But by using a uniform criterion to identify populations and boundaries of urban settlements across the planet, the GHS-UCDB allows for direct comparison of urban settlements populations across disparate geographies and maps the diverse urban settlement patterns to strict fine-grained geographic boundaries requisite to calculating urban population exposure to extreme heat globally.

Data Harmonization

We convert the GHS-UCDB polygons to a raster in the same coordinate reference system (WGS 84) and spatial resolution as CHIRTS-daily T_{max} (0.05° by 0.05°). We then calculate HI_{max} and $WBGT_{max}$ with CHIRTS-daily T_{max} and RH_{min} for 0.05° pixels within each urban settlement from 1983 – 2016 as described below. For each urban settlement, we then area-average HI_{max} and $WBGT_{max}$ for each day in the data record. We recognize the limitations of using an area-average to characterize $WBGT_{max}$ and HI_{max} for an entire urban settlement, especially for large agglomerations that can span multiple climatic zones (6). However, robust global and continental-scale urban heat studies report a single temperature for urban settlements (3, 4, 6). We also note that CHIRTS-daily is available at a finer spatial resolution (Table S1) and has better

spatial and temporal fidelity, than the temperature datasets used in recent global retrospective and predictive extreme temperature studies (3, 4) and UHI effect studies (6).

Daily Urban Heat Index Maximum Estimates

We calculate daily maximum heat index values (HI_{max}) for 0.05° pixels within each urban settlement following the National Ocean and Atmospheric Administration's (NOAA) guidelines (31). First, CHIRTS-daily T_{max} (referred to as T_{max} in eq. 8 - 11 for simplicity) and RH_{min} values are transformed from Celsius to Fahrenheit. Next, daily HI_{max} values are calculated using Steadman's equation and averaged with the T_{max} value (eq. 8):

$$HI_{max} = \frac{(0.5 \times (T_{max} + 61.0 + ((T_{max} - 68.0) \times 1.2) + (0.094 RH_{min})) + T_{max}}{2}$$

(eq. 8)

If the resulting averaged value is greater than 80 F, then we calculate HI_{max} for each city following the complete Rothfusz equation (eq. 9):

$$HI_{max} = -42.379 + 2.04901523 T_{max} + 10.14333127 RH_{min} - 0.22475541 T_{max} RH_{min} - .00683783 T_{max}^2 - 0.05481717 RH_{min}^2 + 0 .00122874 T_{max}^2 RH_{min} + 0.00085282 T_{max} RH^2 - 0.00000199 T_{max}^2 RH_{min}^2$$

(eq. 9)

We then adjust the Rothfusz heat index values per NOAA's guidelines. For a given urban settlement on a given day, if T_{max} is between 80 and 112 °F and RH_{min} <13%, we subtract adjustment 1 from HI_{max} (eq. 10). If T_{max} is between 80 and 87 °F and RH_{min} > 85%, we add adjustment 2 to HI_{max} (eq. 11). We then convert all resulting maximum daily heat index values back to Celsius.

$$ADJ1 = \frac{0.25 \times (13 - RH_{min}) \times \sqrt{(17 - ABS(T_{max} - 95)}}{17} \quad \text{(eq. 10)}$$

$$ADJ2 = \frac{RH_{min} - 85}{10} \times \frac{87 - T_{max}}{5} \quad \text{(eq. 11)}$$

Daily Urban Wet Bulb Globe Temperature Maximum Estimates

Pairwise HI_{max} and $WBGT_{max}$ values fit a quadratic relationship, with HI_{max} estimates above 40.6°C within ±0.5 °C of $WBGT_{max}$ (47), a more complex measure of extreme heat that incorporates radiant heat and air speeds and is widely used to measure occupational limits to heat stress (47). As such, we convert HI_{max} pixels estimates to $WBGT_{max}$ using eq. 12:

$$WBGT\,(°C) = -0.0034\,HI^2\,(°F) + 0.96\,HI\,(°F) - 34 \quad \text{(eq. 12)}$$

Urban Population Exposure to Extreme Heat

We identify urban extreme heat events for two criteria: one day or longer periods where $WBGT_{max}$>30°C and two day or longer periods the maximum HI_{max} >40.6°C. The $WBGT_{max}$ threshold we employ follows the International Standards Organization (ISO) occupational heat stress criteria for risk of heat-related illness among acclimated people with low metabolic rates (125 - 180W) (30, 35). The HI_{max} threshold follows the US National Weather Service's definition for an excessive heat warning (39). We acknowledge that the diversity of heat wave and extreme heat event definitions reflects the wide range of disciplines studying extreme heat (22). Climate scientists tend to use strict thresholds for comparable statistics across the planet, physiologists and occupational health researchers tend to use thresholds tied to local adaptations connected to universal biophysical responses to heat stress (35). Rather than use percentile based criteria to identify heat stress that fit local contexts (18), we employ $WBGT_{max}$ and HI_{max} thresholds for two

primary reasons: (1) to provide consistent estimates of urban heat extreme heat exposure trajectories that can be directly compared across urban geographic and spatial scales, and (2) to capture the contribution to exposure trajectories from both urban population growth and total urban warming using thresholds that have been shown to impact human health and well-being.

Furthermore, unlike extreme heat studies that solely employ 2m air temperature (1), both $WBGT_{max}$ and HI_{max} account for the nonlinear biophysical response to the relationship between humidity and air temperature (3). Core body temperatures are almost universally maintained around 37°C and skin temperatures around 35°C (67). Hyperthermia, elevated core body temperature, occurs when elevated skin temperatures are sustained, which can result in death when core body temperatures reach around 42-43°C (68). While acclimatization can reduce the burden of heat (67, 69), acclimatization only improves sweating mechanisms, and the cooling effects of acclimated people have limits. As relative humidity increases, the evaporative cooling effects of sweating decreases and once relative humidity reaches 100%, sweating continues but evaporative cooling stops. Even acclimated or healthy humans face mortality with prolonged skin temperatures of 37–38°C (70, 71). Thus, it is reasonable that sustained periods of time with HI > 35°C (72) can be physically intolerable and outdoor exposure to $WBGT_{max}$ >30°C has been associated with increased mortality rates among vulnerable populations (37). Accordingly, our exposure thresholds are a conservative estimator, yet comparable globally across spatial scales, of urban population exposure to extreme heat to capture the harmful social (73), health (1), economic (11, 12), and potential political consequences (74) of exposure to extreme heat.

Urban Population Exposure Trends

We quantify urban exposure to extreme heat in person-days yr^{-1} for each GHS-UCDB urban settlement from 1983 - 2016. Person-days yr^{-1} is a widely used metric to compare and contrast exposure to extreme heat across geographies and time periods (4, 40, 75). For a given year (Y_i) and for a given urban settlement (j), we multiply the urban settlement's population (N_{ij}) by the number of days for year i a threshold is exceeded (e.g. $WBGT_{max}$ >30°C, $Days_{ij}$, eq. 13).

After summing exposure in person-days yr^{-1} for each year at municipality, national, regional, and global scales, we evaluate annual rate of increase in exposure from 1983 – 2016 (person-days yr^{-1}) across spatial scales by fitting simple ordinary least squares linear regression models (OLS). For example, at the municipality-level, we estimate the rate of change (β_{exp}) from 1983 - 2016 in person-days yr^{-1} as exposure (Exp_{ij}) for year i from 1983 - 2016 with eq. 14.

$$Exp_{ij} = N_{ij} \times Days_{ij} \text{ (eq. 13)}$$

$$Exp_{ij} = \beta_0 + \beta_{exp} Y_i + \varepsilon \text{ (eq. 14)}$$

Next, we fit simple OLS regression models to estimate the rate of change in the number of days per year where a threshold is exceeded for each urban settlement (eq. 15). For both the rates of increase in exposure and days per year a threshold is exceeded we subset the data to include only urban settlements with statistically significant positive trends ($p < 0.05$).

$$Warming_{ij} = \beta_0 + \beta_{j-days} Y_i + \varepsilon \text{ (eq. 15)}$$

Contribution to Exposure from Population Growth versus Total Urban Warming

We quantify the share of exposure from population growth versus total urban warming for each urban settlement. For a given year i and urban settlement j, the share of person-days yr^{-1}

from total urban warming ($Heat_{ij}$) is calculated by multiplying the urban settlement's population fixed at 1983 by the number of days per year a threshold is exceeded (eq. 16).

$$Heat_{ij} = N_{83j} \times Days_{ij} \text{ (eq. 16)}$$

The share of exposure from population is calculated by multiplying $Days_{ij}$ by the increase in population since 1983 (eq. 17).

$$Pop_{ij} = (N_{ij} - N_{83j}) \times Days_{ij} \text{ (eq. 17)}$$

To measure the rate of change in $Heat_{ij}$and Pop_{ij}, we apply simple OLS regressions to estimate the average rate of increase in person-days yr^{-1}. The resulting coefficients, β_{pop} and β_{heat}, are the average rate of change in person-days yr^{-1} from total urban warming and population growth, respectively. We use these coefficients to generate a bounded index to measure the relative share in the increase of exposure from urban population growth versus total urban warming from 1983 - 2016. To this end, for a given urban settlement *j*, we subtract the rate of person-day increase from population-growth (β_{pop}) from the rate of person-day increase due to warming (β_{heat}) and divide the result by the annual increase in coefficient of exposure (β_{exp}, eq. 18). We then normalize the index and plot the distribution of this index for at for all municipalities (Fig. 2C, Fig. S5C) and by region (Fig. 3, Fig. S6).

$$Index = (\beta_{pop} - \beta_{heat}) \div \beta_{exp} \text{(eq. 18)}$$

Identifying Heat Waves

Our dataset includes more than 150 million area-averaged daily T_{max}, RH_{min}, $WBGT_{max}$, and HI_{max} observations spanning more than 13,000 urban settlements from 1983 to 2016. As

such, we produced a comprehensive inventory of urban extreme heat events across the two thresholds employed, for all urban settlements as a derivative product that identifies the duration, intensity, magnitude and dates of all urban extreme heat events worldwide from 1983 - 2016. The entire dataset is searchable by English-language municipality names, country, and region (including sub- and intermediate-regions) and made publicly available for scholars and practitioners to identify extreme heat events based on the criteria of their choosing (22).

Uncertainty and Limitations

We recognize that, aside from our linear regression models, the results are presented as point estimates without uncertainty. Yet all of the underlying data are from complex fusions of various different data sources. The underlying data products being used lack characterization of uncertainty and thus prevent us from estimating uncertainty in our results. Because of this, our analysis focuses on distinct and extreme differences in the patterns we identify that are representative estimates of the true signals of the underlying processes. Given the fine-grained spatiotemporal resolution of our analysis, our results provide crucial improvements of previous coarse-scale data on total urban warming (4, 40) and urban population growth trends (27) that are key for future climate change scenario planning (21), adaptation development (6) and early warning system development (20).

Data and materials availability

All data and code produced are publicly available on Github: https://github.com/ecohydro/GlobalUrbanHeat. CHIRTS-daily T_{max} and the relative humidity product are available from UCSB Climate Hazard Center FTP site: ftp://ftp.chc.ucsb.edu/pub/org/chc/products/CHIRTSdaily/v1.0/global_tifs_p05/

Global Human Settlement Layer Urban Centers Database (GHS-UCDB) is available from the

European Commission JRC: https://ghsl.jrc.ec.europa.eu/datasets.php

Acknowledgments: The authors would like to thank Prof. Susan Cassels for providing an internal review of this manuscript and the Earth Research Institute computing staff for the tireless assistance throughout this project. We also thank two anonymous reviewers for their excellent feedback. CT was supported by the UC Presidential Dissertation Year Fellowship through UC Santa Barbara and the Earth Institute Postdoctoral Fellowship Program, Columbia University. CT, KC and TE, received support from NSF awards SES-1801251, SES-1832393, DEB-1924309. Support for CF and PP came from the National Aeronautics and Space Administration (NASA) GPM mission grant #80NSSC19K0686, the United States Agency for International Development (USAID) cooperative agreement #72DFFP19CA00001 and the Famine Early Warning Systems Network and the Defense Advanced Research Projects Agency (DARPA) World Modelers Program under Army Research Office (ARO) prime contract no. W911NF-18-1-0018.

Figure Legends

Fig. 1. Global urban population exposure to extreme heat, defined by one day or long periods where WBGTmax >30°C, from 1983 – 2016 (A), with the contribution from population growth (B) and total urban warming (C) decoupled.

Fig. 2. (A) Municipality-level increase in the rate of urban population exposure to extreme heat from 1983 - 2016 and (B) the rate of increase in the total number of days per year where $WBGT_{max}$ > 32°C. (C) The share of population versus total urban warming in the rate of increase of total population exposure using WBGTmax > 30°C. Fig. S4 zooms in on Southern India, Ganges Delta, Nile river valley and delta, and Tigres-Euphrates river valley. Note, the largest

increase in exposure (A) and days per year WBGT >30°C (B) are rendered last for emphasis. In (C), urban settlements with a greater contribution from total urban warming (e.g. pink) are rendered last for emphasis.

Fig. 3. The comparative contribution to the increase in the rate of urban exposure to extreme heat due to population growth versus total urban warming varies considerably across selected regions using $WBGT_{max}$ > 30 °C threshold.

Fig. 4 Two examples – Kolkata, India in 1998 (A and B) and Aleppo, Syria in 2010 (C and D) – previously poorly or undocumented documented urban heat waves that our analysis uncovered. In both cases, the contrast between daily HI_{max} (A and C) with $WBGT_{max}$ (B and D) estimates shows that, while HI was not designed to be accurate at values HI_{max} > 50°C, $WBGT_{max}$ does not capture the amplitude of daily extremely hot temperature-humidity combinations.

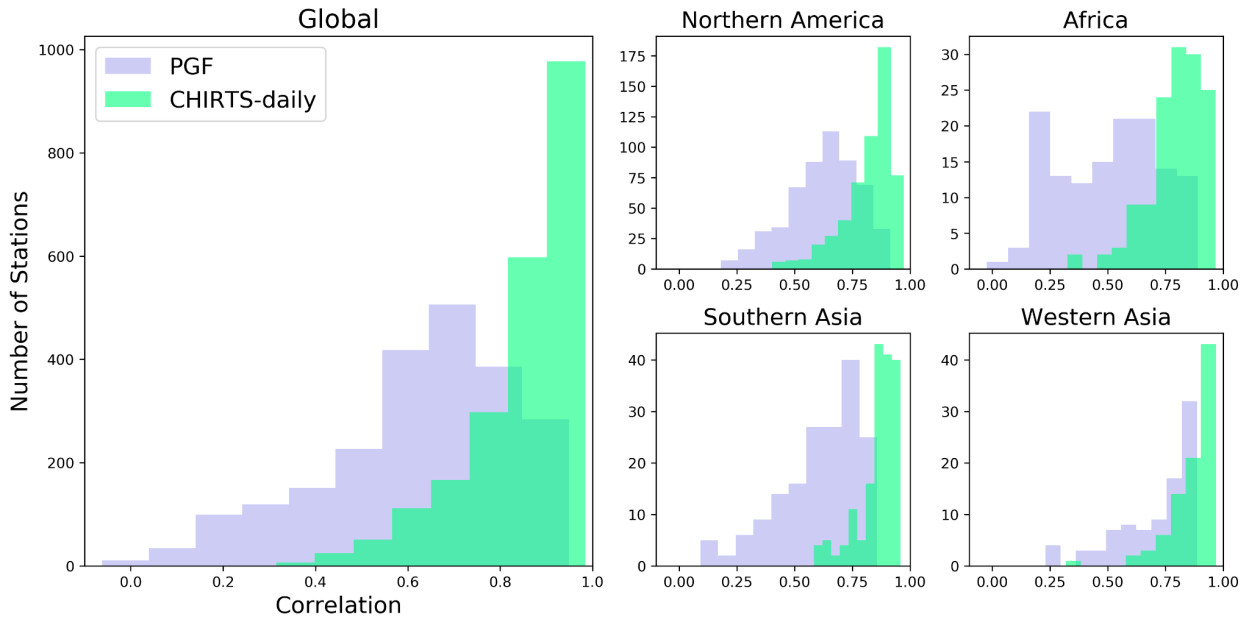
Supplementary Text

Fig. S7 provides examples of exposure trends at the country-level for Nigeria, China and Italy, separating the contribution from total urban warming and urban population growth as shown globally in Figure 1 of the main text. These three examples highlight how geographic variation—including levels of development, country population sizes, and urban settlements located across a range of climate zones within each country (1)—affect national-level exposure trajectories. Both China and Nigeria are both rapidly urbanizing (2). As such, urban population growth explains much of the national-level exposure trajectories. Unlike in China, where the national-level contribution from total urban warming is less pronounced (Fig. S7), we find that in Nigeria the exposure trajectory is also clearly being affected by total urban warming (Fig. S7). In Italy, populations across all urban settlements are stable or declining (2). Thus, any increase in total urban warming will drive the overall increase in exposure (Fig. S7).

As we zoom into municipality-level exposure, our analysis reveals heterogeneous spatial patterns of how urban population growth and total urban warming drive exposure trajectories within a given country, especially those that span climate gradients (Fig. S8). Take three examples of large Nigerian cities (Fig S8): Lagos, Abuja, and Kano. These three cities cover diverse climate zones across Nigeria's north-south gradient. While all three have experienced rapid population growth since 1983, the trend for exposure and total urban warming varies across the three cities. For Lagos, which is coastal, the effect of the annual increase in the number of days per year where $WBGT_{max}$ >30°C on the city's exposure trajectory is apparent. Similarly, Kano, which is in the north and borders the Sahara Desert, has experienced a more rapid increase in the number of days per year where $WBGT_{max}$ >30°C. In contrast, Abuja, which is centrally located and experienced rapid population growth like Lagos and Kano, rarely experienced any days from 1983 - 2016 where $WBGT_{max}$>30°C and thus it has no significant exposure trend.

The contrast in exposure trajectories between countries and across urban settlements within a country highlights the importance of fine-resolution, yet globally comprehensive urban extreme heat exposure analysis presented here. Indeed, our results and data capture the diverse spatial patterns requisite to pinpoint and compare exposure trajectories to aid the development of adaptation strategies (1) and early warning systems (3). This is especially important given finite resources and the various tradeoffs of adaptation to reduce the impacts of urban extreme heat exposure (4, 5).

Fig. S1 Distribution of correlation statistics (R^2) for urban CHIRTS-daily T_{max} and



Princeton University's Global Meteorological Forcing Dataset (PGF) T_{max} with urban Global Historical Climatology Network and Global Summary of the Day databases. CHIRTS-daily T_{max} outperforms PGF globally and in crucial rapidly urbanizing regions, such as Africa, Southern Asia, Western Asia, that lack station observations for the majority of urban settlements (Fig. S3). Figure was reconstructed with data from (4).

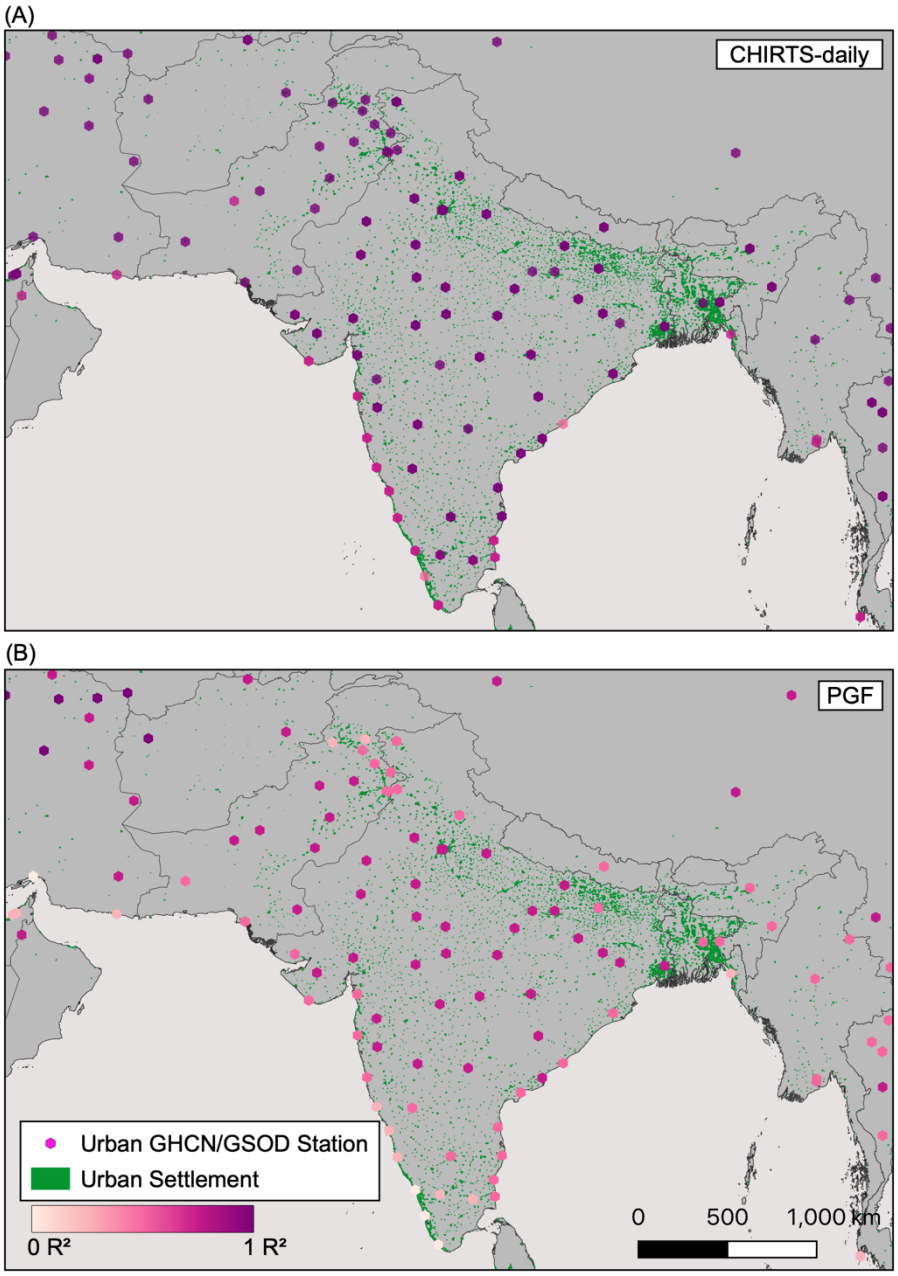


Fig. S2. Correlation (R2) for CHIRTS-daily T_{max} and Princeton University's Global Meteorological Forcing Dataset (PGF) T_{max} with urban Global Historical Climatology Network and Global Summary of the Day databases for Southern Asia. Much of the region's urban areas lack station observations. For example, in India, of 3,248 urban

settlements, only 111 have GHCN/GSOD stations with a robust reporting record (4). At 0.05° spatial resolution, CHIRTS-daily provides accurate, high resolution urban T_{max} estimates for rapidly urbanizing regions like Southern Asia that lack widespread urban station observations and improves over previous datasets like PGF.

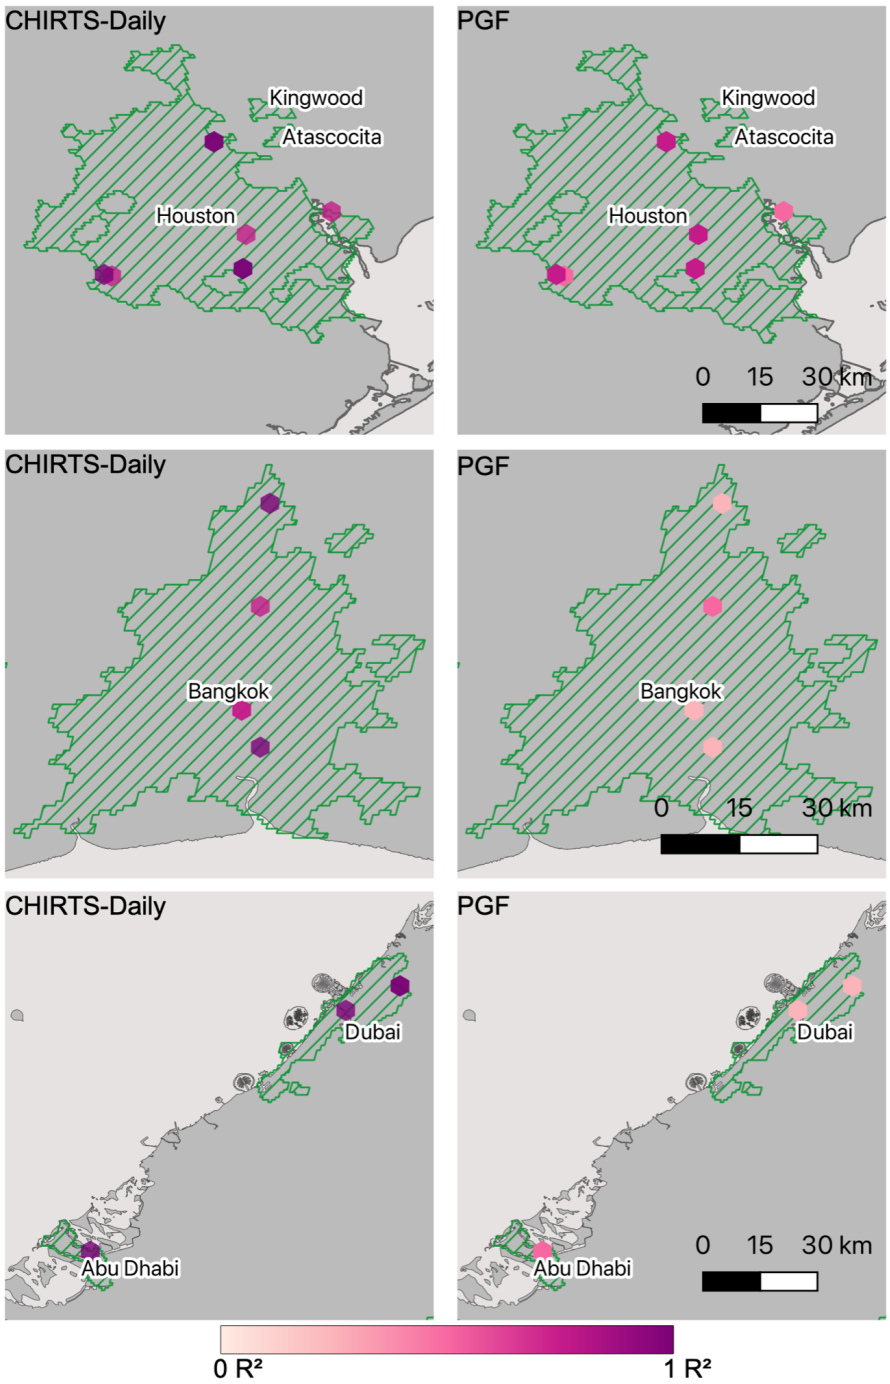

Fig. S3 Correlation (R2) for CHIRTS-daily T_{max} and Princeton University's Global Meteorological Forcing Dataset (PGF) T_{max} with urban Global Historical Climatology

Network and Global Summary of the Day databases for the Houston, Bangkok, Dubai, and Abu Dhabi metropolitan areas. All four urban settlements had a significant exposure trend from 1983 - 2016 using a threshold of $WBGT_{max} > 30°C$. Across these diverse urban contexts, CHIRTS-daily better captures the urban T_{max} signal than PGF and provides accurate T_{max} estimates.

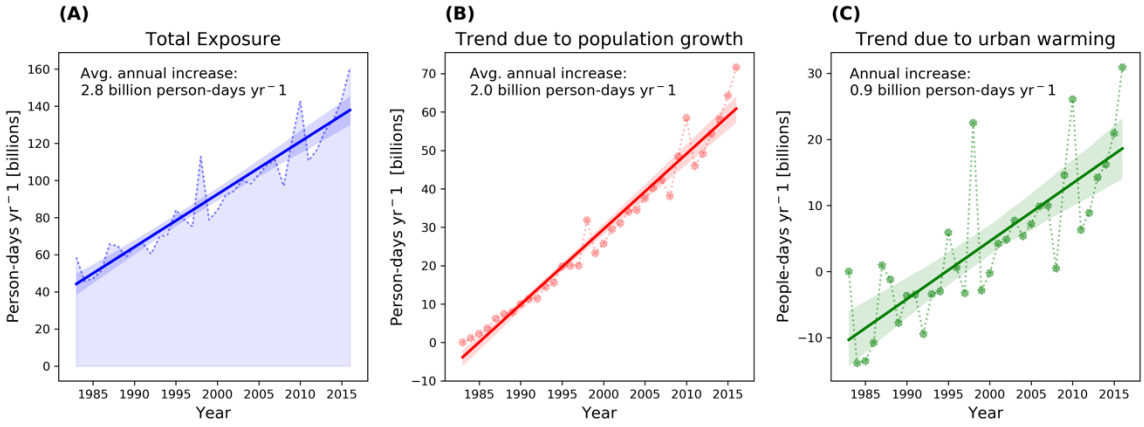

Fig. S4. Global urban population exposure to extreme heat from 1983 – 2016 (A), with the contribution from population growth (B) and total urban warming (C) decoupled. Extreme heat exposure is defined by urban population exposed to two days or longer periods where $HI_{max} > 40.6°C$.

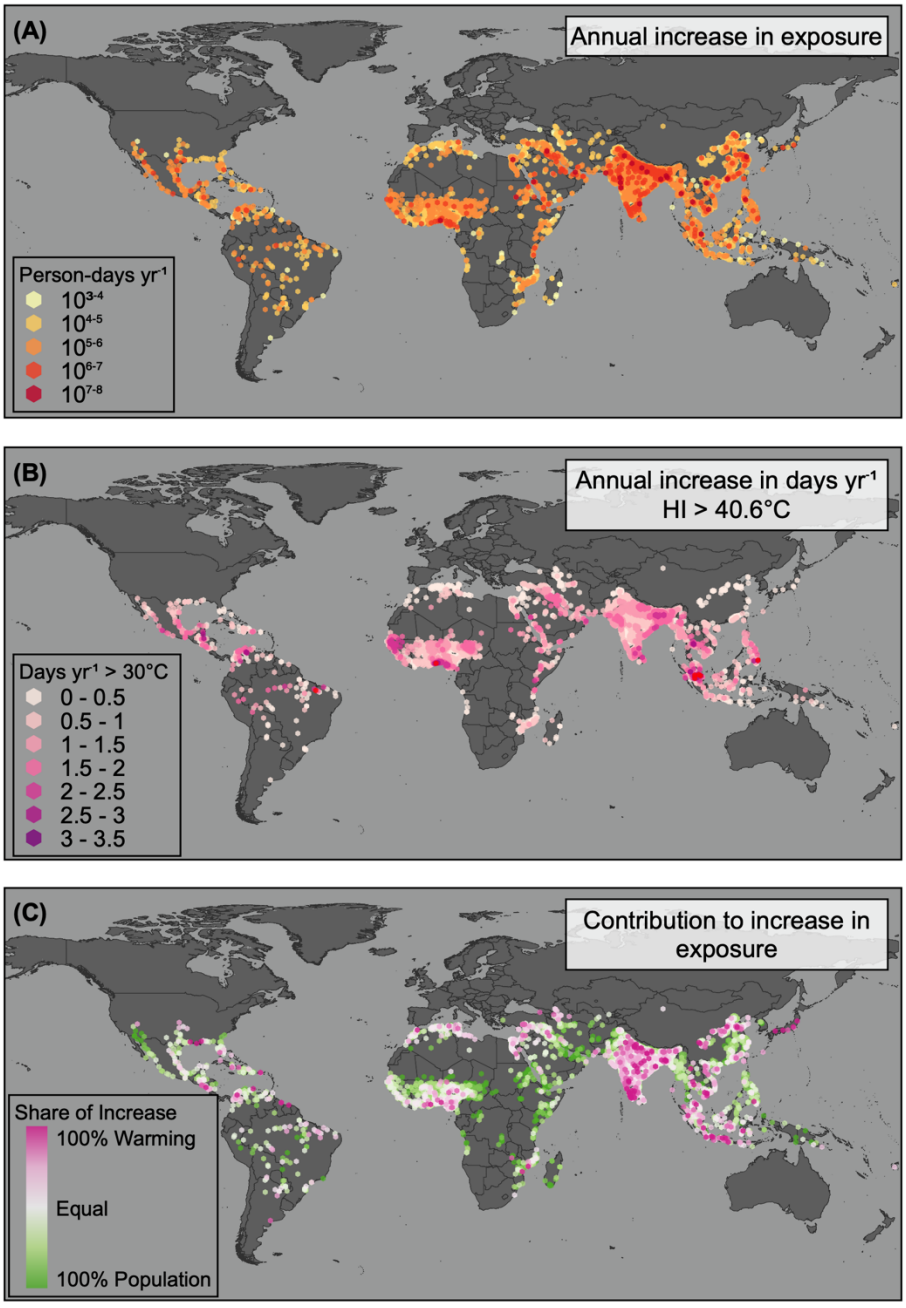

Fig. S5. (A) Municipality-level increase in the rate of urban population exposure to extreme heat from 1983 - 2016 and (B) the rate of increase in the total number of days per year where $HI_{max} > 40.6°C$ (C). Note, the largest increase in exposure (A) and days per year $HI_{max} > 40.6$ °C (B) are rendered last for emphasis. In (C), urban settlements with a greater contribution from total urban warming (e.g. pink) are rendered last for emphasis. Extreme heat exposure is defined by urban population exposed to two days or longer periods where $HI_{max} > 40.6°C$.

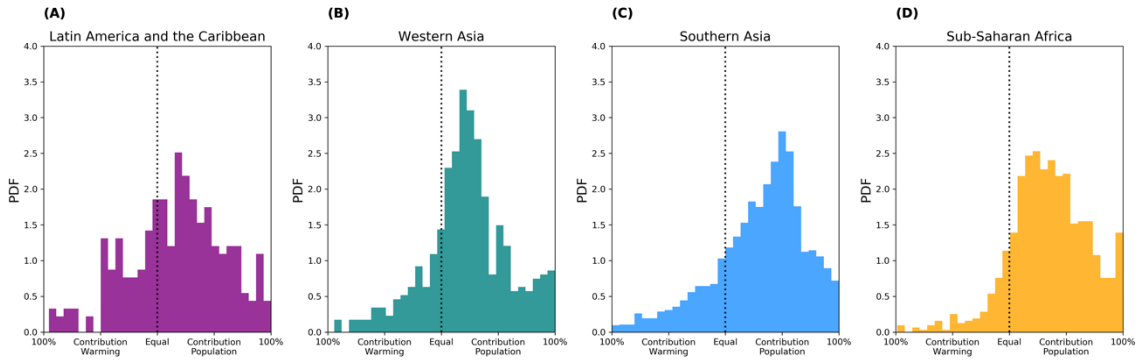

Fig. S6. The comparative contribution to the increase in the rate of urban exposure to extreme heat due to population growth versus total urban warming varies considerably across selected regions when extreme heat exposure is defined by urban population exposed to two days or longer periods where $HI_{max} > 40.6°C$.

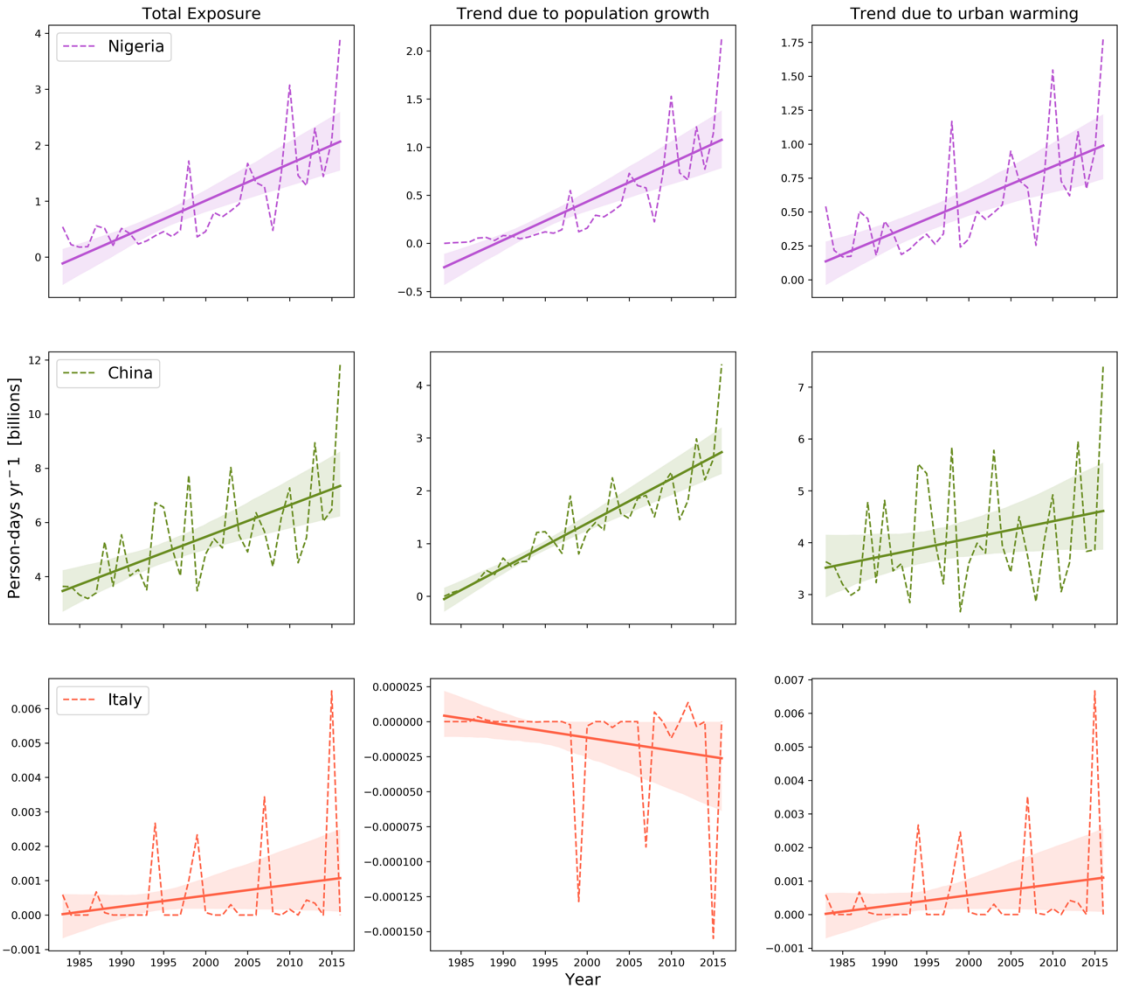

Fig. S7. National-level total urban warming exposure trajectories from 1983 – 2016 with the contribution from total urban warming and urban population growth separated for Nigeria, China and Italy. $WBGT_{max}$>30°C threshold is used to define extreme heat exposure.

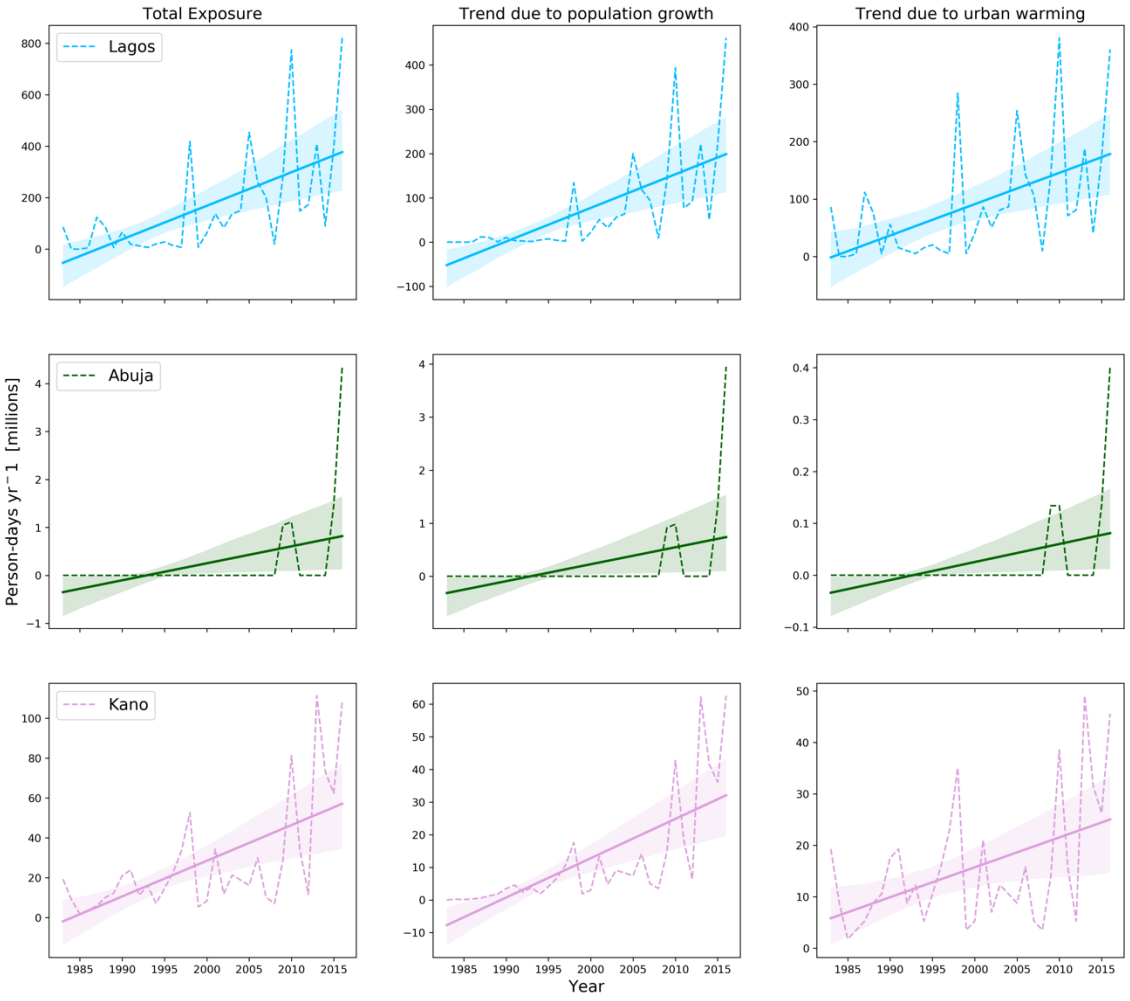

Fig. S8. Municipality-level total urban warming exposure trajectories from 1983 – 2016 with the contribution from total urban warming and urban population growth separated for three large Nigerian cities—Lagos, Abuja, and Kano. $WBGT_{max}$>30°C threshold is used to define extreme heat exposure.

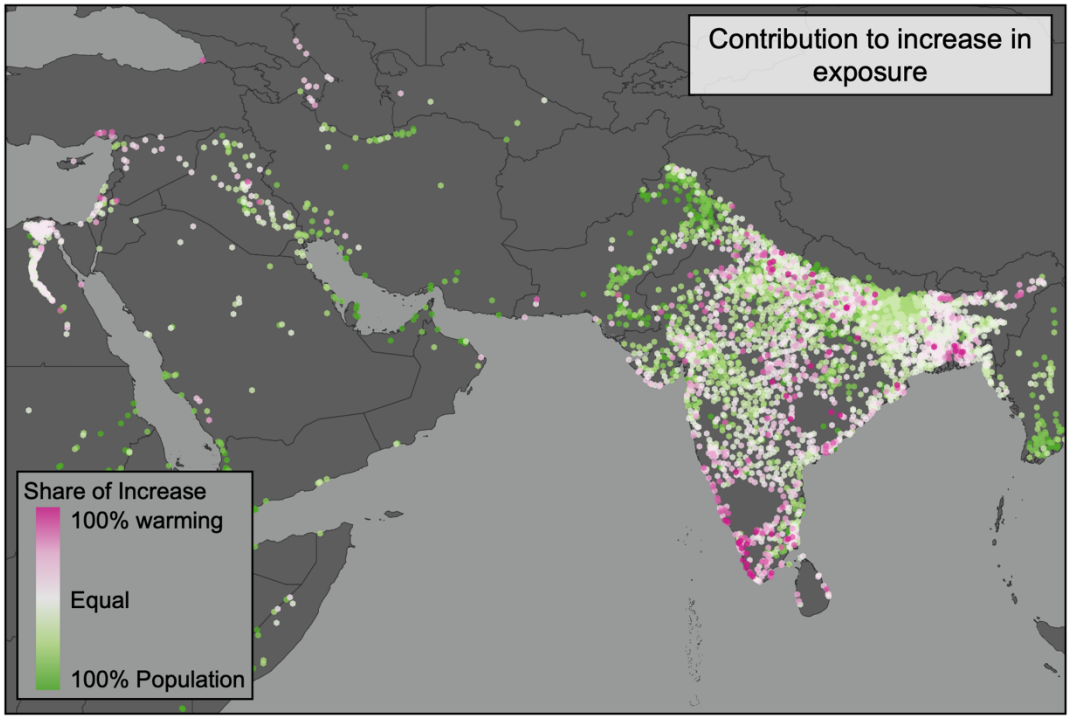

Fig. S9. Zoomed in from Fig. 2C. The share of population versus total urban warming in the rate of increase of total population exposure in Southern India, Ganges Delta, Nile river valley and delta, and Tigris-Euphrates river valley using $WBGT_{max}$ > 30°C. Total urban warming drove exposure trajectories in urban settlements in coastal southwestern India and southern Indonesia, though rapidly urbanizing regions. Note, urban settlements with a greater contribution from total urban warming (e.g. pink) are rendered last for emphasis. $WBGT_{max}$>30°C threshold is used to define extreme heat exposure.

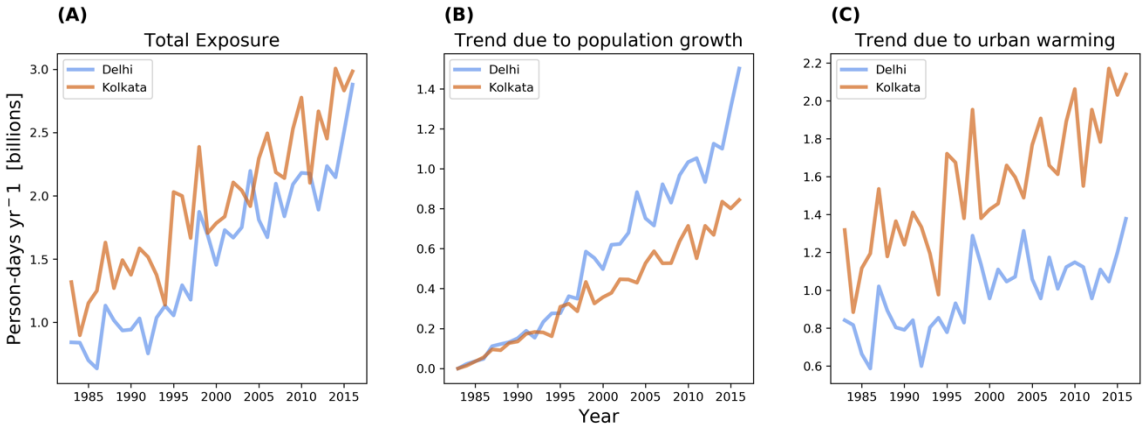

Fig. S10. (A) Total urban population exposure to extreme heat from 1983 – 2016 for Delhi and Kolkata, with the contribution from (B) population growth and (C) total urban warming decoupled. $WBGT_{max}$>30°C threshold is used to define extreme heat exposure.

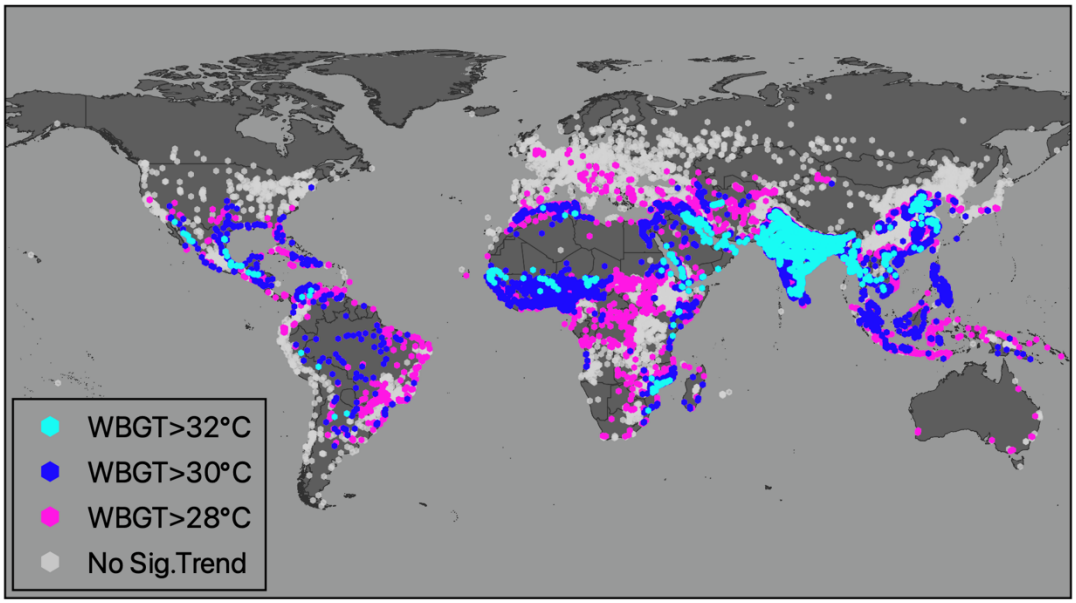

Fig. S11 Urban settlements with a significant ($p < 0.05$) increase in exposure from 1983 - 2016 for daily threshold of $WBGT_{max} > 32°C$ (2,979) urban settlements, turquoise), $WBGT_{max} > 30°C$ (5,985 urban settlements, blue), $WBGT_{max} > 28°C$ (7,628 urban settlements, pink), and no exposure trend measured at these thresholds (5,507 urban settlements, gray).

Table S1: Recently published global extreme heat studies. All studies use temperature input data that is coarser resolution than CHIRTS-daily (4) and those that use PGF or ERA5 likely underestimate extreme heat (4). The two studies (5, 6) that measure baseline population exposure do not delineate urban from rural exposure, nor assess how exposure trajectories have changed over time.

Year Published	Heat Metric(s)	Population Exposure Baseline Measured?	Temperature Data	Spatial Resolution	Reference
2021	3 day or longer periods where daily minimum air temperatures (T_{min}) > 99th percentile of daily T_{min} over baseline (1985 - 2005)	Yes, global persons > 65 years old 1980 - 2020	ERA5	0.5° × 0.5°	(5)
2020	Wet-bulb temperature > 35°C	No	HadISD	point data	(7)
2020	Variable - models heat-mortality relationship globally	No	PGF, BEST	administrative boundaries	(8)
2017	Plots daily maximum air temperatures (T_{max}) against relative humidity (RH) to identify mortality risk (person-days)	Yes, global total population ~2000	NCEP-DOE Reanalysis 2	1.5° × 1.5°	(6)
2017	Wet-bulb temperature 30 - 35°C (person-days)	No, projected exposure only	NCEP-DOE Reanalysis 2	2° × 2°	(9)
2017	Heat index > 40.6°C (person-days), standard wet bulb globe temperature > 35°C SWBGT, and dry bulb > 37.6°C	No, only subset of 44 cities reported	ERA-Interim	0.5° × 0.5°	(10)

2017	Apparent heat wave index, new percentile-based metric that combines temperature and humidity	No	ERA-Interim, Reanalysis 2	1.875° × 1.875°	(11)
2016	Wet bulb globe temperatures (WBGT)	No, focuses on lost labor productivity	CRU	0.5° × 0.5°	(12)

Table S2. Regions ranked by annual rate of increase in exposure from 1983 – 2016, with the percent of the global exposure trend, as well as percent contribution from total urban warming and urban population growth to the total exposure trajectories for each country using $WBGT_{max}$ > 30°C.See Materials and Methods for link to the entire dataset.
